## Abstract

The enumeration of finite models of first order logic formulas is an indispensable tool in computational algebra. The task is hindered by the existence of isomorphic models, which are of no use to mathematicians and therefore are typically filtered out a posteriori. This paper proposes a divide-and-conquer approach to speed up and parallelize this process. We design a series of invariant properties that enable us to partition existing models into mutually non-isomorphic blocks, which are then tackled separately. The presented approach is integrated into the popular tool Mace4, where it shows tremendous speed-ups for a variety of algebraic structures.

## 1 Introduction

There are many types of relational algebras (groups, semigroups, quasigroups, fields, rings, MV-algebras, lattices, etc.) using operations and relations of many arities, but the overwhelming majority of the most popular only use operations of arity at most 2; in the words of two famous algebraists, *It is a curious fact that the algebras that have been most extensively studied in conventional (albeit modern!) algebra do not have fundamental operations of arity greater than two.* (See page 26 of [4])

To study and get intuition on them, mathematicians resort to libraries of all order  $n$  models of the algebra they are interested in (for small values of  $n$ ). These libraries allow experiments such as testing and/or forming conjectures etc., to gain insights. Therefore, it comes as no surprise that GAP [8], the most popular computational algebra system, has many such libraries. For groups it has the list of almost all small groups up to order a few thousands and the list of all primitive groups up to degree a few thousands, among others; for semigroups it has the list of all small models up to order 8 [6]; for quasigroups up to order 6 [16]; there is also a library of Lie algebras and many others. These libraries are so important that the search for them has a long history in mathematics predating for many

---

\* Preprint, or original in the proceedings of CP 2021.

42 years the use of computers. For example, the search for libraries of degree  $n$  primitive groups  
 43 started long ago: Jordan (1872) for  $n \leq 7$ ; Burnside (1897) for  $n \leq 8$ ; Manning (1906-1929)  
 44 for  $n \leq 15$ ; Sims (1970) for  $n \leq 20$ , Pogorelov (1980) for  $n \leq 50$ ; Dixon and Mortimer (1988)  
 45 for  $n \leq 1000$ . (See Appendix B of [7]; and for more recent results in OEIS [17]).

46 Many more such libraries are needed. For example, SMALLSEMI [6] has the list of  
 47 semigroups up to order 8 (there are too many semigroups of order 9 to be storable), but  
 48 if we impose extra properties on the semigroup (such as being inverse, a band, regular, or  
 49 Clifford, etc. — there are tens of classes of semigroups —) their numbers decrease and hence  
 50 libraries of models of higher orders could be produced and stored.

51 Many of these algebras can be defined in first order logic (FOL) and there are tools  
 52 to allow mathematicians to encode their algebras and produce a meaningful library. The  
 53 problem is that usually the tools that can be easily learned and used by mathematicians  
 54 generate too many isomorphic models, thus wasting time generating redundant models and  
 55 then wasting more time to get rid of them. For example, Mace4 [13], a very popular finite  
 56 model enumerator among mathematicians due to its very intuitive and user-friendly language,  
 57 would produce 28,947,734 inverse semigroups of order 8 when given the following simple  
 58 first-order formulas as input [1] (with binary operation  $*$  and unary operation  $'$ ).

$$59 \quad \begin{aligned} (x * y) * z &= x * (y * z). & (x * x') * x &= x. & 0 * 0 &= 0. \\ ((x * x') * y) * y' &= ((y * y') * x) * x'. & x'' &= x. \end{aligned}$$

60 During the search, the number of output models in this example is already greatly reduced  
 61 by the Least Number Heuristic (LNH) and the special symmetry breaking input clause  
 62  $0 * 0 = 0$ . Out of the almost 29 millions output models, only 4,637 ( $\approx 0.016\%$ ) are pairwise  
 63 non-isomorphic. The proportion of non-isomorphic models in the outputs tends to get smaller  
 64 very fast as the order of the algebraic structure goes higher.

65 Redundant models may either be eliminated during search or filtered out afterwards.  
 66 Guaranteeing that search never produces isomorphic models is a hard problem and is rarely  
 67 seen in modern solvers. This paper therefore tackles the second problem, i.e., the removal of  
 68 redundant models from an already enumerated set.

69 In our context, the complexity of checking whether two models are isomorphic is only  
 70 part of the problem. Another source of complexity is the large number of models that need  
 71 to be checked. If all pairs of models are checked, the performance degrades rapidly as the  
 72 total number of models increases (see Section 5).

73 To tackle this problem, we explored many different strategies eventually concluding that  
 74 the best one is to assign to every generated model a vector that is invariant under isomorphism.  
 75 This allows us to partition the output with all the isomorphic models living inside the same  
 76 block (or part). This splits the problem into substantially smaller sub-problems. Moreover,  
 77 processing inside each block can easily be done in parallel as models across blocks cannot  
 78 be isomorphic. This is an important facet of the approach since modern-day computers are  
 79 more often than not equipped with multiple cores.

80 What made this project take off was the identification of a large number of general  
 81 algebra properties invariant under isomorphism coupled with experiments to identify a small  
 82 subset of these properties without losing discriminating power. This approach will help  
 83 mathematicians on two levels: first, it provides them with a tool on their desktop that quickly  
 84 produces a library for the algebra they are working with; second, the tool may be run on a  
 85 cluster of computers to pre-compute libraries for the most famous classes of algebras, and  
 86 add them to GAP [8] or a similar system.

87 Our contributions to the area of isomorphic model elimination are (see Section 3):

- 88 ■ Devise an invariant-based algorithm that can be applied to algebras defined in FOL and  
 89 containing at least one binary operation.
- 90 ■ Design a small set of invariant properties that in practice have high discriminating power,  
 91 and yet are inexpensive to compute.
- 92 ■ Use a hash-map to store models partitioned by the invariant-based algorithm to allow  
 93 fast storage and retrieval of models in the same block.

94 We apply the proposed partitioning technique to Mace4's isomorphic model filtering  
 95 programs, and observe orders of magnitude speed-up in its isomorphic model elimination  
 96 step (see Section 4).

## 97 2 Mathematical Background

98 Algebra is a pair  $(A, \Omega)$ , where  $A$  is a set and  $\Omega$  is a set of operations, that is, functions  
 99  $f : A^n \rightarrow A$  (in this case  $f$  is said to be an operation of arity  $n$ ). Let  $A = (D, *_A)$  and  
 100  $B = (D, *_B)$  be two algebras, each with one binary operation on a finite domain (or universe)  
 101  $D$ . An isomorphism of these two algebras is a bijective function  $f : A \rightarrow B$  such that  
 102  $f(a *_A b) = f(a) *_B f(b)$ , for all  $a, b \in A$ . Two models are said to be isomorphic if there exists  
 103 an isomorphism between them. The relation  $A$  is isomorphic to  $B$  is clearly an equivalence  
 104 relation and hence induces a partition of the algebras considered. Only one representative  
 105 algebra in each block is needed.

106 The definition of isomorphism can easily be extended to cover algebras with multiple  
 107 binary operations. Formally, suppose  $A$  and  $B$  are algebras of type  $(2^m, 1^n)$ , where  $m, n$   
 108 are non-negative integers; then we can assume that the binary operations are  $(*_1, \dots, *_m)$   
 109 and the unary operations are  $(g_1, \dots, g_n)$ . An isomorphism between them is a bijection  
 110  $f : A \rightarrow B$  such that  $f(a *_i b) = f(a) *_i f(b)$ , for all  $a, b \in D$  and every binary operation  $*_i$ ,  
 111 and for any unary operation  $g_i$ , we have  $f(g_i(a)) = g_i(f(a))$ , for all  $a \in D$ .

## 112 3 Invariant-based Algorithm

113 Let  $A$  and  $B$  be two algebras and  $f : A \rightarrow B$  an isomorphism between them; in addition,  
 114 suppose  $e^2 = e \in A$  is an idempotent. Then  $f(ee) = f(e)$  implies that  $f(e)f(e) = f(e)$ , that  
 115 is,  $f(e)$  under an isomorphism is also an idempotent. As isomorphisms map idempotents onto  
 116 idempotents, it follows that the number of idempotents in  $A$  must be smaller or equal to the  
 117 number of idempotents on  $B$ . Since the inverse of an isomorphism is an isomorphism,  $A$  and  
 118  $B$  must have the same number of idempotents. We call these properties that are preserved  
 119 by isomorphisms (such as the *number of idempotents*) *invariant properties* or *invariants* for  
 120 short. These invariant properties are the basis of our proposed algorithm.

121 Guided by fundamental concepts heavily appearing in different parts of mathematics,  
 122 we design 10 invariant properties that collectively have high discriminating powers, and yet  
 123 are inexpensive to compute. For a binary operation in a model with finite domain  $D$ , we  
 124 compute the invariant properties for each domain element  $x$  as:

- 125 1. The smallest integer  $n$  such that  $x^n = x^k$ ,  $n > k \geq 1$  where we define  $x^n$  to be  
 126  $(\dots(x * x) * x) * x \dots$  for  $n$   $x$ 's (*periodicity*).
- 127 2. The number of  $y \in D$  such that  $x = (xy)x$  (*number of inverses*).
- 128 3. The number of distinct  $xy$  for all  $y \in D$  (*size of right ideal*).
- 129 4. The number of distinct  $yx$  for all  $y \in D$  (*size of left ideal*).
- 130 5. 1 if  $xx = x$ , 0 otherwise (*idempotency*).
- 131 6. The number of  $y \in D$  such that  $x(yy) = (yy)x$  (*number of commuting squares*).

- 132 7. The number of  $y \in D$  such that  $x = yy$  (*number of square roots*).
- 133 8. The number of  $y \in D$  such that  $x(xy) = (xx)y$  (*number of square associatizers*).
- 134 9. The number of pairs of  $y, z \in D$  such that  $zy = yz = x$  (*number of symmetries*).
- 135 10. The number of  $y \in D$  such that there exists pairs of  $s, t \in D$  where  $x = st$  and  $y = ts$
- 136 (*number of conjugates*).

137 Invariant 5 is the idempotent property of the domain element and is preserved by  
 138 isomorphisms as discussed before. The correctness of invariants in general hinges on the  
 139 following lemma (folklore). Let  $F$  be a FOL formula on the signature of the algebra and  
 140  $M$  and  $M'$  two isomorphic models. It holds that the sets  $S$  and  $S'$  defined by  $F$  in  $M$  and  
 141  $M'$ , respectively, are of the same cardinality. This is because the isomorphism induces a  
 142 bijection between the two sets (*cf.* Theorem 1.1.10 in [12]). In other words, invariants based  
 143 on solution counting are guaranteed to be correct.

144 We call the ordered list of invariant properties so calculated the invariant vector of that  
 145 domain element. Each model with  $n$  domain elements will be associated with  $n$  invariant  
 146 vectors. Isomorphic models must have the same set of invariant vectors.

147 To facilitate comparisons of invariant vectors, we sort the invariant vectors by the  
 148 lexicographical order of their elements (see the example below for more explanations). It  
 149 follows that models isomorphic to each other must have the same sorted invariant vectors. If  
 150 the model has multiple binary operations, then invariant vectors are calculated for each of the  
 151 binary operations, and all the invariant vectors of the same domain element are concatenated  
 152 to form a combo invariant vector for that domain element. The combo invariant vectors will  
 153 then be sorted to yield the final ordered list of invariants.

154 Often we are not only to compare 2 models for isomorphism, but to extract all non-  
 155 isomorphic models from a list of models. In that case, we set up a hash map to store the  
 156 blocks of the models. We use the invariant vectors for each model to send the model quickly  
 157 to the block (in the hash map) to which it belongs. That is, the keys in this hash map  
 158 are the invariant vectors, and the values are the blocks of the models. After all models are  
 159 hashed into the hash map, the blocks stored in the hash map can be processed separately,  
 160 and possibly in parallel, to extract one representative model from each isomorphism class.

161 Note that our invariant-based algorithm does not compare models for isomorphism. It  
 162 only cuts down the size of the problem to improve the speed of existing isomorphism filters  
 163 such as Mace4's *isofilter*.

164 As an example to show how invariant vectors are constructed and used, suppose we want  
 165 to find all non-isomorphic models in a list of 3 quasigroups,  $A$ ,  $B$ , and  $C$ , of order 4. Suppose  
 further that their domain is  $D = \{0, 1, 2, 3\}$  and their operation tables are given in Table 1.

■ **Table 1** Operation tables of Quasigroups  $A$ ,  $B$  and  $C$

Model A					Model B					Model C				
*A	0	1	2	3	*B	0	1	2	3	*C	0	1	2	3
0	0	1	2	3	0	0	1	2	3	0	0	1	2	3
1	1	0	3	2	1	1	2	3	0	1	1	0	3	2
2	2	3	1	0	2	2	3	0	1	2	2	3	0	1
3	3	2	0	1	3	3	0	1	2	3	3	2	1	0

166 The 10 invariant properties can easily be calculated for each of the domain elements of  
 167 these models. Note that while the invariant vector for each domain element is calculated  
 168 separately, it is not important exactly which domain element gives a particular invariant  
 169 vector. It is the set of invariant vectors as a whole that matters.

Invariant vectors of Model A	Invariant vectors of Model B	Invariant vectors of Model C

■ **Figure 1** Lexicographically sorted invariant vectors with discerning properties highlighted.

171 Next we sort the invariant vectors of each model by their elements lexicographically.  
 172 Invariant vectors of models *A* and *C* need no change as they are already in the desired sort  
 173 order. Invariant vectors of model *B* will be in sort order by interchanging the invariant  
 174 vectors of elements 1 and 2, which are the second and third row. The final invariant vectors  
 175 are shown in the Figure 1. Note that the first column in the tables is the domain element,  
 176 and the next 10 columns are its invariant properties.

177 The highlighted numbers in the figure are the discerning invariant properties in the  
 178 example. All other invariant properties are the same from domain element to domain element.  
 179 For example, Invariant properties 3, *size of right ideal*, and 4, *size of left ideal*, always equal  
 180 to the size of the domain *D* because the operation table of a quasigroup is a Latin square.  
 181 This highlights the need for multiple invariant properties targeting different areas of algebraic  
 182 structures to increase their collective discriminating powers. In fact, our algorithm depends  
 183 more on the orthogonality of the invariants than on the splitting power of any one individual  
 184 invariant. See Table 2 for the top invariants in different algebras.

185 It should be easy to see that models *A* and *B* have the same sorted invariant vectors,  
 186 and thus are possibly isomorphic to each other. They are indeed isomorphic to each other  
 187 because applying the permutation (1, 2) to model *B* will give model *A*. However, invariant  
 188 vectors alone cannot prove that they are isomorphic models. It is also easy to see that the  
 189 invariant vectors of model *C* are different from those of the other 2 models, and from this  
 190 fact alone, we can conclude that model *C* is not isomorphic to any of *A* and *B*.

191 Finally, for ease of comparison and hashing, we concatenate the sorted invariant vectors  
 192 into a single string. The string representation of the invariant vectors for the models are:

193  $A, B: 2,1,4,4,1,4,2,4,4,1,3,1,4,4,0,4,2,4,4,1,5,1,4,4,0,4,0,4,4,1,5,1,4,4,0,4,0,4,4,1$   
 194  $C: 2,1,4,4,1,4,4,4,4,1,3,1,4,4,0,4,0,4,4,1,3,1,4,4,0,4,0,4,4,1,3,1,4,4,0,4,0,4,4,1$

195 Since we are to extract all non-isomorphic models from this list of models, we use the string  
 196 representations of the invariant vectors as the keys for the hash map. Both models *A* and *B*  
 197 will therefore go to the same block in the hash map, but *C* will go to a different block. Now  
 198 that all 3 models are deposited in their blocks in the hash map, each block can be processed  
 199 separately in parallel as we only need to compare models in the same block for isomorphism.  
 200 This step can be performed by many existing programs such as Mace4's isomorphism filters  
 201 (see Section 4).

202 Finally, if the models have multiple binary operations, we compute the unsorted invariant  
 203 vectors for each binary operation as described above, then concatenate the invariant vectors  
 204 of the same domain element into one combo invariant vector, sort these combo invariant  
 205 vectors in lexicographical order, and finally concatenate the sorted invariant vectors into  
 206 their string format.

207 It is important to note that the hash map in our algorithm obviates the need to compare  
 208 invariant vectors among the models during the partitioning process. If we do pairwise

209 comparison of models by their invariant vectors in any step, we would end up with a  $O(n^2)$   
 210 worst-case scenario.

## 211 4 Experimental Results

212 We have implemented an invariant-based pre-processor to the Mace4’s isomorphic models  
 213 filters. We run the experiments on a 6-core Intel®Core™ i7-9850H CPU computer. We  
 214 shall show results of tests on 3 algebraic structures, namely, quasigroup, inverse semigroup,  
 215 and quandle [1]. They are chosen because of their importance in the mathematical world.  
 216 Quasigroup is the most prominent non-associative algebra, inverse semigroup is probably  
 217 the most studied associative algebra with a unary operation, and quandles is probably most  
 218 important algebra with 2 binary operations.

219 The results show that when the size of the output models is more than just a few hundreds  
 220 of thousands, the invariant vectors often give an order or two magnitudes of improvements in  
 221 the speed of the isomorphism elimination process even without running them in parallel. A  
 222 very desirable feature of our algorithm is that the improvement increases dramatically as the  
 223 size of the problem grows. Furthermore, Mace4’s *isofilter2* is not able to handle input size  
 224 beyond a few million quasigroups of order 6 (see Table 2), but our invariant-based algorithm  
 225 can partition the models into smaller blocks of sizes within Mace4’s limits.

■ Table 2 Isomorphism Eliminations

	Order	# of Mace4 Outputs	Time (s)	
			With Invariants	Without Invariants
Quasigroups	5	10,944	1	1
	6	11,543,040	1,182	N/A
Inverse Semigroups	5	2,151	<1	<1
	6	38,828	3	2
	7	929,923	73	81
	8	28,947,734	2,873	150,703
Quandles	6	1,833	2	1
	7	22,104	6	374
	8	359,859	450	267,463

226 We show the results of the non-parallel runs to demonstrate the improvements due solely  
 227 to the invariant vectors. The performance can be improved further if the blocks are processed  
 228 in parallel. For example, the processing time for the biggest block for quandles of order 8 is  
 229 only 20 seconds, so if we have enough processors to process all the blocks in parallel, then  
 230 the processing time can theoretically be cut down close to  $24 + 19.937 \approx 44$  seconds from  
 231 450 seconds, more than 90% reduction (see Table 3).

232 One reason for the dramatic improvement in the run-time by our invariant-based algorithm  
 233 is that the invariant vectors chosen have great discriminating power as shown by the fact  
 234 that the average number of non-isomorphic models per block is very close to 1 (see Table 4).  
 235 The top 4 contributing invariants for the highest order of each class are also listed in Table 4.

■ **Table 3** Isomorphism Eliminations in Parallel

	Order	#Blocks	Time (s)	
			Generating Invariants	Processing Biggest Block
Quasigroups	6	1,129,129	265	0.0106132
Inverse Semigroups	8	4,582	1,031	2.807
Quandles	8	1,143	24	19.937

■ **Table 4** Discriminating Power of Invariant Vectors

	Order	#Blocks	Non-isomorphic Models		
			Total	Avg per Block	Top 4 Invariants
Quasigroups	5	1,402	1,411	1.01	
	6	1,129,129	1,130,531	1.00	6, 1, 8, 10
Inverse Semigroups	5	52	52	1.00	
	6	208	208	1.00	
	7	908	911	1.02	
	8	4,582	4,637	1.01	9, 3, 2, 1
Quandles	6	66	73	1.11	
	7	250	298	1.19	
	8	1,143	1,581	1.38	8, 3, 6, 10

## 5 Related Work

237

238 The proposed approach falls into the class of *divide-and-conquer* algorithms; most notably  
 239 Heule et al. [10] recently applied the *cube-and-conquer* approach [9] to solve the Boolean  
 240 Pythagorean triples problem.

241 There are a large number of techniques to break symmetries during the search phase [5],  
 242 such as the Least Number Heuristic (LNH) [18] and the eXtended LNH (XLNH) [2]. The  
 243 LNH, for example, is a very popular dynamic symmetry breaker implemented in Mace4,  
 244 FALCON [18], and SEM [19], etc., to help reduce the number of isomorphic models. However,  
 245 these techniques do not guarantee isomorph-freeness. Systems that try to generate isomorph-  
 246 free models, such as SEMK [3, 14] and SEMD [11], are either yet to be complete, or are  
 247 better off allowing some isomorphic models in the outputs for some problem sets. Thus, post-  
 248 processing tools such as our invariant-based algorithm have an important role in isomorphism  
 249 elimination as total elimination of isomorphism in the model search phase may not always  
 250 be the best option.

251 Invariants are widely used under different guises in many branches of mathematics. For  
 252 example, in graph theory, node invariants can be used to help detect isomorphic graphs [15].  
 253 Interestingly, similar ideas can be seen in Mace4’s isomorphism filters. Indeed, Mace4’s  
 254 *isofilter* uses the numbers of occurrences of domain elements in the operation tables as the  
 255 lone invariant that serves 2 purposes: First is to do quick checks for non-isomorphism, as  
 256 models having different occurrences of domain elements cannot be isomorphic. Second is  
 257 to guide the construction of isomorphic functions between potential isomorphic models, as  
 258 domain elements can only map to domain elements having the same occurrences in the  
 259 operation tables. This reduces the number of permutations to try in the search of isomorphic

260 functions. However, the lone invariant in *isofilter* would fail miserably if the models are  
 261 quasigroups for which each domain element would appear the same of times in the operation  
 262 table. To mitigate this problem, Mace4 provides another isomorphism filter, *isofilter2*, which  
 263 transforms the models to their canonical forms based on the same algorithm [14] given by  
 264 McKay as mentioned above in SEMK. Compared to *isofilter*, *isofilter2* performs much better  
 265 for quasigroups, but worse on other algebraic structures such as semigroups due to its high  
 266 overheads in computing canonical forms. Nevertheless, both filters compare every model  
 267 against the list of non-isomorphic models found so far, and hence their performances degrade  
 268 rapidly as the number of models increases. Therefore, both filters benefit immensely from  
 269 the reduced number of models in the blocks created by our invariant-based algorithm.

270 The *loops* package [16] in GAP [8] uses invariant vectors of 9 invariants in many of its  
 271 isomorphism-related functions. Like Mace4's *isofilter*, it uses invariant vectors to check for  
 272 non-isomorphism, and to help guide the construction of isomorphic function between models  
 273 using sophisticated algorithms that take advantage of other GAP functions. Their invariant  
 274 vectors work on only one operation table, and exploit heavily specific properties of quasigroups  
 275 and loops, which may be ineffective in other kinds of algebras. Our invariant-based algorithm  
 276 targets different aspects of all algebraic structures including quasigroups, semigroups, and  
 277 more. It also works with multiple binary operations, and does not rely on any built-in  
 278 functionality of GAP. Moreover, given a list of models to find non-isomorphic models, the  
 279 *loops* package would compare the invariant vector of every model against those of the list of  
 280 all non-isomorphic models found so far to get the list of potential isomorphic models. Our  
 281 hash map-based organization of models eliminates the need to compare invariant vectors  
 282 repeatedly because all models having the same invariant vectors are already grouped into  
 283 the same block in the hash map.

## 284 **6 Future Work and Conclusions**

285 Currently, we only compute invariants based on binary operations, which are by far the most  
 286 prevalent operations in algebraic structures [4]. However, unary operations are also quite  
 287 common, and may be even less expensive to manipulate. The discriminating power of the  
 288 invariant vectors of the model can be enhanced with the addition of invariant vectors based  
 289 on unary operations, and will be part of our future focus.

290 The results of our research open a whole new line of research into using invariant properties  
 291 to eliminate isomorphism in finite model enumeration:

- 292 ■ Identify more invariant properties and the cases for which each of them may be useful.
- 293 ■ Allow dynamic, and preferably automatic, selection of invariant properties to use in any  
 294 given algebraic structure because different invariants work best for different algebraic  
 295 structures (see example in Section 3, and also Table 4), so we need to allow dynamic,  
 296 and preferably automatic, selection of invariant properties.
- 297 ■ Find the best sets of invariant properties to use for various sizes and types of models. A  
 298 larger set of algebras (usually of higher orders) may need more invariants in the invariant  
 299 vectors to provide enough discriminating power to separate the models into smaller blocks,  
 300 but a smaller set of algebras may incur too much overhead in computing the invariant  
 301 vectors with many invariant properties.

302 We observe that the invariant-based algorithm is efficient, scalable, and parallelizable.  
 303 It is also compatible with most, if not all, existing finite model enumerators. The focus of  
 304 future research will be on finding more good invariant properties, in binary and in unary

operations, to be used as partitioning keys, and on adding the capability of dynamic and automatic selection of invariant properties to use.
